### BEARING STRENGTHS OF SOME WROUGHT-ALUMINUM ALLOYS

By R. L. Moore and C. Wescoat

#### INTRODUCTION

Although a number of investigations of the bearing strength of aluminum alloys have been made (see references 1 and 2), the problem remains one of considerable interest to the aircraft industry. For this reason it has seemed advisable to make additional tests of the commonly used aircraft alloys in an effort to establish a better basis for the selection of allowable bearing values. Current design practice does not recognize the effect of edge distance upon bearing strengths, and for this reason edge distance was one of the principal variables considered in this investigation. The increasing emphasis being placed upon permanent set limitations makes it essential that more information on bearing yield phenomena be obtained.

The object of this investigation was to determine bearing yield and ultimate strengths of the following aluminum alloy products: 17S-T, 24S-T, Alclad 24S-T, 24S-RT, 52S-O, 52S-1/2H, 52S-H, 53S-T, and 61S-T sheet; A51S-T and 14S-T forgings; and 24S-T, 53S-T and 61S-T extrusions. Ratios of these bearing properties to tensile properties were also determined.

#### MATERIAL

The sheet used for these tests was 0.064- by 10- by 20-inch. Bearing specimens were cut parallel to the 20-inch dimension, which was also parallel to the direction of rolling. The extruded material was obtained in the form of die No. K-22934. Figure 13 shows a sketch of this section and indicates the portion used for the bearing specimens. The forgings were obtained in the form of 1/4-

by 3- by 12-inch samples which were machined to a 1/8-inch thickness for test.

The tensile properties given in table I indicate that the material used was typical of commercial production. The ultimate strengths ranged from 7 to 17 percent higher than the guaranteed minimums (see reference 3); the yield strengths (with-grain for sheet) were from 11 to 30 percent higher than the latter. In only one case (53S-T sheet) was the elongation value (with-grain) less than that specified.

### PROCEDURE

The bearing tests involved loading single thicknesses of material in bearing on a 0.250-inch-diameter steel pin, inserted in close-fitting drilled and reamed holes. All specimens were 2 inches wide and were tested in triplicate. The sheet specimens were loaded in the direction of the grain. The tests were conducted in the 40,000-pound capacity Amsler testing machine (type 20 ZBDA, serial no. 4318) using the loading fixture shown in figure 1.

The measurements of hole elongation under increasing loads were made with a filar micrometer microscope, reading directly to 0.01 millimeter and by estimation to 0.002 millimeter. These measurements were taken between two reference marks: one scribed on a shoulder on the underside of the pin, in the plane of the sheet; the other scribed on the specimen directly under the pin. Edge distances, defined as the distance from the edge of the specimen to the center of the hole in the direction of loading, were 1.5, 2, and 4 times the pin diameter. Tests at all three edge distances were made on each specimen by shearing or sawing off the damaged end after one test (about 3/4 in. below the center of the damage hole), and redrilling at a new edge distance.

### RESULTS AND DISCUSSION

Table II gives the results of all the bearing tests. The bearing yield-strength values were obtained from the bearing stress-hole elongation curves shown in figures 2

to 15, using an offset from the initial straight-line portion of the curves equal to 2 percent of the pin diameter (0.005 in.). Table II also indicates the types of failure obtained. For edge distances of 1.5 and 2 times the pin diameter, failures occurred by shearing or tearing out a portion of the specimen in the margin above the pin. For edge distances of 4 times the pin diameter, failures occurred by upsetting and crushing the metal above the pin for all cases except the forgings, which failed in shear as for the smaller edge distances.

One of the primary objects of this investigation was to obtain information to aid in establishing typical ratios of bearing to tensile properties for the aluminum alloys commonly used in aircraft. Table III summarizes the average ratios obtained. These results have been arranged according to similarity of bearing-strength characteristics into two fairly well-defined groups: group 1, including the alloys having tensile strengths ranging from 64,500 to 77,900 pounds per square inch; and group 2, including the alloys having tensile strengths ranging from 28,600 to 47,300 pounds per square inch. Ratios of tensile yield to ultimate strength averaged 0.79 for the first group; 0.90 for the second, excluding 52S-O. As would be expected, there are a few borderline cases where the bearing-strength ratios might be placed in either group, but, in general, the highest ratios of bearing ultimate and yield strength to tensile strength for all edge distances were obtained for the alloys within the lower range of tensile strengths; the lowest ratios were obtained for the highest strength materials.

The relative importance of the various properties influencing bearing strengths is, of course, not known. It seems reasonable to assume that the highest ratios of bearing ultimate to tensile strength should be exhibited by materials having low ratios of tensile yield to ultimate strength, combined with ductility or the ability to withstand highly localized plastic deformations without fracture. Of the materials in group 2, showing the highest ratios of bearing ultimate to tensile strength, 52S-O is the only one meeting both of these requirements. The ratios of tensile yield to ultimate strength of the other materials in group 2 are, with one exception, higher than for group 1, yet the influence of this factor was apparently more than offset as far as ultimate bearing strengths were concerned by the greater ductility of

the lower strength alloys. The superior forming characteristics of this group of materials are generally recognized.

Bearing-yield strengths, it appears, should be related in some way to the other yield-strength characteristics of a material. Although the state of stress developed by a pin or rivet in bearing is obviously complex, it is not surprising that the bearing-yield to tensile-strength ratios shown in table III increase with increasing ratios of tensile yield to tensile strength. From the approximately linear relationship observed between these ratios for both groups of materials, it follows that the ratios of bearing-yield to tensile-yield strength for any one edge distance should be fairly constant. The uniformity of these ratios suggests that they provide a simpler and perhaps a more rational basis for expressing bearing-yield characteristics than do ratios of bearing-yield strength to tensile strength which, as shown, may vary appreciably for different materials.

One of the interesting observations to be made from the results of these tests is that the increases in bearing-yield strengths for edge distances greater than 2 diameters were not as pronounced as in the case of the ultimate bearing strengths. This was particularly true of the materials in the lower tensile-strength group. At an edge distance of 2 diameters, moreover, the bearing-yield strengths averaged about two-thirds of the ultimate bearing strengths. According to present aircraft-design procedures, in which the stress at yielding generally controls design if it is less than two-thirds of the ultimate strength (ultimate factor of safety = 1.5), it appears that bearing yield rather than bearing ultimate strength will be the controlling factor in designs for edge distances greater than 2 diameters.

It should be emphasized in connection with any analysis of these data for design purposes that the bearing strengths given were all obtained from tests of 2-inch-wide specimens, 0.064 to 0.125 inch thick, loaded parallel to the direction of the grain through a 1/4-inch-diameter steel pin. Under other test conditions somewhat different bearing values would have been obtained. Table IV gives a few data from other tests relative to the effect of specimen proportions and direction of loading upon the bearing properties of 24S-T sheet. Of principal interest is the fact that the ratios of bearing-yield to tensile-yield strength were higher for the cross-grain direction (X) than

for the with-grain direction (W). These cross-grain ratios may be approximated by multiplying the with-grain ratios by the ratios of the tensile yield strength with-grain to that across-grain.\* Ratios of bearing ultimate strength to tensile strength for the cross-grain direction may likewise be estimated by multiplying the with-grain ratios by the ratio of the tensile strength with-grain to that across-grain. It is concluded from these observations that actual values of bearing yield and ultimate strength (not ratios to tensile properties) show no significant directional characteristics. This result is consistent with the indications of earlier bearing tests.

Table IV also indicates that the bearing-yield strengths obtained from specimens having a gross width equal to four times the pin diameter ( $W = 4D$ ) were essentially the same as found for specimens having a width of  $8D$ , which was the width proportion used for the tests of this investigation. The ultimate bearing strengths of the specimens having a width of  $4D$  were about 5 percent less than obtained for the wider specimens.

Ratios of pin diameter to material thickness ( $D/t$ ) apparently have little effect upon bearing strengths, provided  $D/t$  equals 4 or less. For relatively larger pin diameters, decreases in ultimate bearing strength may be expected as shown in table IV. Although not indicated in the table, bearing-yield strengths are not influenced by ratios of  $D/t$  provided the required yield strain ( $0.02D$ ) can be produced before ultimate bearing failure occurs.

Table V gives a summary of the ratios selected from table III as a tentative basis for predicting nominal bearing values for the alloys and products considered. It should be emphasized that the ratios proposed for sheet materials are based on bearing and tensile tests made in the with-grain direction. Since bearing properties do not show marked directional characteristics it follows that ratios of bearing to tensile properties across-grain will be somewhat higher than shown in table III. The greatest difference will be found in the case of ratios of bearing yield to tensile yield strength, since the latter property for certain cases is normally higher in the with-grain direction than in the cross-grain direction.

---

\*See table I-1, ANC-5, 1942, for relations between with- and cross-grain properties of aluminum-alloy sheet.

The ratios given for 17S-T and plain and Alclad 24S-T sheet in table V are in substantial agreement with values obtained in previous bearing tests of these alloys in the form of sheet. The ratios given for the thin 24S-T extruded sections, however, are not necessarily representative of the behavior likely to be obtained in thicker extrusions. Table V includes, for example, a set of ratios recently obtained for  $3\frac{1}{4}$ -inch thick 24S-T extruded sections having a large percentage of unrecrystallized material with tensile strengths slightly over 80,000 pounds per square inch. The ratios of bearing to tensile properties for this 24S-T were appreciably lower than any obtained in the present tests. Comparative data for thick and thin forgings of A51S-T and 14S-T are not available.

It is quite evident from table V that one set of ratios of bearing to tensile properties cannot be given to cover adequately all the wrought-aluminum alloys in their various commercial forms. The ratio of bearing ultimate strength to tensile strength of approximately 1.4 currently used for most alloys in aircraft design (see reference 4) is satisfactory for edge distances of 1.5 diameters but appears unduly conservative for edge distances of 2 diameters or greater. It is believed that the influence of edge distance should be recognized in the selection of allowable bearing values.

### CONCLUSIONS

The results of this investigation of the bearing-strength characteristics of a number of aluminum alloys in the form of sheet, thin extrusions, and thin forgings, loaded in bearing through a steel pin,  $1/4$  inch in diameter, seem to warrant the following conclusions:

1. The bearing-strength data presented were obtained from materials representative of commercial production. Table I gives a summary of tensile properties.
2. Table II gives bearing yield and ultimate strengths for all materials for edge distances of 1.5, 2 and 4 times the diameter of the pin. Although the highest bearing values were obtained for the largest edge distance, the increases in bearing-yield strengths for edge distances greater than 2D were not as pronounced as in the case of the ultimate strengths.

3. Bearing-yield strengths are apparently related to the other yield characteristics of a material and therefore tend to approach an upper limiting value as edge distances are increased. Bearing ultimate strengths, however, reflect the ability of a material to withstand highly localized plastic deformations without fracture. Because of the upsetting that may occur ahead of the pin, accompanied by an increase in effective bearing area, extremely high values of ultimate bearing strength may be obtained for large edge distances in ductile materials.

4. All specimens with edge distances of 1.5 and 2 times the diameter of the pin failed by shearing or tearing out a portion of the specimen in the margin above the pin. Specimens with edge distances of 4 diameters failed in bearing by crushing or upsetting the metal above the pin, except in the case of the forgings which failed in shear, as for the smaller edge distances.

5. The ratios of bearing yield and ultimate strength to tensile strength given in table III indicate that all the materials tested may be placed in two rather well defined groups: one including the alloys having tensile strengths ranging from 64,500 to 77,900 pounds per square inch; the other including the alloys having tensile strengths ranging from 28,600 to 47,300 pounds per square inch. The highest ratios of bearing to tensile strength were found for the materials in the lower tensile-strength range.

6. Ratios of bearing yield to tensile ultimate strength varied almost linearly with ratios of tensile yield to ultimate strength. Ratios of bearing-yield to tensile-yield strength, however, were practically constant for all materials, particularly for edge distances of 1.5D and 2D. Tensile-yield strengths therefore appear to provide a simpler and perhaps a more rational basis for expressing bearing-yield characteristics than do tensile ultimate strengths.

7. From a limited number of tests of 24S-T sheet, summarized in table IV, and the results of an earlier investigation, it appears that bearing yield and ultimate strengths do not exhibit marked directional characteristics. In view of the difference which exists in some cases between tensile-yield strengths in the with- and cross-grain directions, ratios of bearing-yield to tensile-yield strengths in the cross-grain direction may be higher than shown in table III for the with-grain direction.

8. Bearing-yield strengths determined from auxiliary specimens having a gross width of only four times the pin diameter were essentially the same as determined from specimens having a width of 8 diameters, the proportion used in these tests. Ultimate bearing strengths for specimens having a width of  $4D$  were about 5 percent less than for a width of  $8D$ . Ratios of pin diameter to material thickness ( $D/t$ ) had little effect upon either bearing yield or ultimate strengths for values of  $D/t$  equal to 4 or less. For higher  $D/t$  ratios, decreases in bearing ultimate strengths must be expected, as shown in table IV.

9. Table V presents the ratios of bearing-to-tensile properties proposed from these tests as a tentative basis for predicting nominal bearing values for the aluminum alloys and products considered.

10. Edge distance is a sufficiently important factor to be recognized in the selection of allowable bearing values. It is believed that consideration of this factor will permit some increase in bearing values over those currently used in design.

Notes - All tests on 1/4-in. diam. steel pin (D/t, 4 or less). Specimens 2 in. wide, loaded parallel to direction of grain. \*Original thicknesses of material except for 148-T and A518-T, in which cases specimens were machined from 1/4- by 3- by 12-in. forged stock. †Type of failure (B) Bearing, (S) Shear.

brive percent alclad coating on each side. \*Stress corresponding to offset of 2 percent of hole diam. from initial straight line portion of load-hole elongation curves shown in figs. 2 to 15. (0.005 in. offset for 1/4-in. diam. pin)

**TABLE IV**  
EFFECT OF SPECIMEN PROPORTIONS AND DIRECTIONS OF LOADING UPON RATIOS OF BEARING

\* I - cross-grain, W - with-grain.

**TABLE V**  
SUGGESTED TYPICAL RATIOS OF BEARING TO TENSILE PROPERTIES  
(P. T. No. 040642-C)

Product	Edge distance - 1.5 x pin diameter		Edge distance - 2 x pin diameter		Edge distance - 4 x pin diameter	
	TS	TYS	TS	TYS	TS	TYS
17S-T sheet 24S-T sheet Alc. 24S-T* sheet 24S-RT sheet	1.5	1.4	1.9	1.6	2.3	1.7
52S-O sheet 52S-1/2H sheet 52S-H sheet 53S-T sheet 61S-T sheet	1.6	1.4	2.1	1.6	3.0	1.6
24S-T thin extrusions	1.5	1.4	1.9	1.6	2.3	1.7
24S-T thick extrusions	1.2	1.2	1.5	1.4	2.1	1.6
53S-T thin extrusions 61S-T thin extrusions	1.6	1.4	2.1	1.6	3.0	1.6
14S-T thin forgings	1.5	1.4	1.9	1.6	2.3	1.7
A51S-T thin forgings	1.6	1.4	2.1	1.6	3.0	1.6

Above ratios are based on tests of 2-in. wide specimens, loaded parallel to direction of grain on 1/4-in. diameter steel pin. (D/t = 4 or less). Corresponding ratios for sheet across grain are higher by ratio of tensile yield or ultimate strength with-grain to that across-grain.  
Ratios for "thin" extrusions are based on tests of specimens from section 0.070 in. thick (Die No. K-22934).  
Ratios for "thick" extrusions are based on tests of specimens from section approximately 3-3/4 in. thick (Die No. K-27768).  
Ratios for "thin" forgings are based on tests of specimens from forged plates, 1/4 x 3 x 12 in.

\* 5 per cent Alclad coating on each side.

Figure 1.- Arrangement for bearing tests using filar micrometer microscope for measurements of hole elongation.

Pin diameter =  $1/4$  in.  
 Sheet thickness = 0.064 in.  
 Specimen width = 2 in.

A-1, A-2 and A-3: edge distance =  $4 \times$  pin diameter  
 B-1, B-2 and B-3: edge distance =  $2 \times$  pin diameter  
 C-1, C-2 and C-3: edge distance =  $1.5 \times$  pin diameter

Figure 2.- Bearing stress-hole elongation curves for aluminum alloy sheet, 17S-T.

Pin diameter =  $1/4$  in.  
 Sheet thickness = 0.064 in.  
 Specimen width = 2 in.

A-1, A-2 and A-3: edge distance =  $4 \times$  pin diameter  
 B-1, B-2 and B-3: edge distance =  $2 \times$  pin diameter  
 C-1, C-2 and C-3: edge distance =  $1.5 \times$  pin diameter

Figure 3.- Bearing stress-hole elongation curves for aluminum alloy sheet, 24S-T.

Pin diameter = 1/4 in.

Sheet thickness = 0.064 in.

Specimen width = 2 in.

A-1, A-2 and A-3: edge distance = 4× pin diameter

B-1, B-2 and B-3: edge distance = 2× pin diameter

C-1, C-2 and C-3: edge distance = 1.5× pin diameter

Figure 4.- Bearing stress-hole elongation curves for aluminum alloy sheet, alodad 24S-T.

Pin diameter = 1/4 in.

Sheet thickness = 0.064 in.

Specimen width = 2 in.

A-1, A-2 and A-3: edge distance = 4× pin diameter

B-1, B-2 and B-3: edge distance = 2× pin diameter

C-1, C-2 and C-3: edge distance = 1.5× pin diameter

Figure 5.- Bearing stress-hole elongation curves for aluminum alloy sheet, 24S-RT.

Figure 6.- Bearing stress-hole elongation curves for aluminum alloy sheet, 52S-0.

Figure 7.- Bearing stress-hole elongation curves for aluminum alloy sheet, 52S-1/2H.

Pin diameter =  $1/4$  in.  
 Sheet thickness = 0.064 in.  
 Specimen width = 2 in.

A-1, A-2 and A-3: edge distance =  $4 \times$  pin diameter  
 B-1, B-2 and B-3: edge distance =  $2 \times$  pin diameter  
 C-1, C-2 and C-3: edge distance =  $1.5 \times$  pin diameter

Figure 8.- Bearing stress-hole elongation curves for aluminum alloy sheet, 52S-H.

Pin diameter =  $1/4$  in.  
 Sheet thickness = 0.064 in.  
 Specimen width = 2 in.

A-1, A-2 and A-3: edge distance =  $4 \times$  pin diameter  
 B-1, B-2 and B-3: edge distance =  $2 \times$  pin diameter  
 C-1, C-2 and C-3: edge distance =  $1.5 \times$  pin diameter
